Docket No. 000560.00123

# PERIPHERAL LENGTH CORRECTION DEVICE OF METAL RINGS

## BACKGROUND OF THE INVENTION

The present invention relates to a peripheral length  
5 correction device of metal rings, and more particularly to a  
peripheral length correction device used to correct the  
peripheral length of metal rings which constitute a V-belt type  
continuously variable transmission belt (hereinafter referred  
to as "CVT belt").

10 Conventionally, there is a known CVT belt which is structured  
by layering about ten thin metal rings of 0.2 mm thickness in  
succession with steel metal elements inserted therein. For  
example, as disclosed in "REALIZATION OF THE IDEAL MAXIMUM  
PERFORMANCE OF A CVT TRANSMISSION" by Tomomi Miyaji, [on line],  
15 [searched on August 25, 2002], Internet <URL: [http://  
www.idemitsu.co.jp/lube/cvtbody2.html](http://www.idemitsu.co.jp/lube/cvtbody2.html)> and illustrated in FIG.  
4 of this homepage.

The CVT belt of such a structure is manufactured as follows.  
First, the ends of the thin sheet metal, which are made of super  
20 strong steel such as maraging steel, are welded together to form  
a ring-shaped drum. The drum is then cut into the predetermined  
width and rolled out to constitute metal rings of a predetermined  
peripheral length. The metal rings are then subjected to a  
solution treatment or the like. This is followed by a peripheral  
25 length correction process, which is carried out by a "peripheral  
length correction device" to correct the metal rings to an accurate

peripheral length. The metal rings are further subjected to an aging treatment, nitriding and the like to enhance their hardness. A plurality of such metal rings (about ten mentioned above) which vary slightly in peripheral length from one to the other are mutually layered to form a CVT belt. Thus, the peripheral length correction device is an important and indispensable device to carry out the lamination of multiple thin metal rings to form one CVT belt.

As a conventional peripheral length correction device, there is known device which carries a solution treated and the like metal rings (hereinafter referred to as "receiving correction rings") laid on two rollers (driving roller and driven roller) of which either or both are displaceable in mutually separating directions while rotating the rollers, and thereby applying tensile stress to the receiving correction rings to correct their peripheral length. This device is described in Japanese Laid-Open (Kokai) Patent Application (A) numbered 2001-105050 titled "METHOD FOR PERIPHERAL LENGTH CORRECTION OF METAL RINGS."

The conventional peripheral length correction device is useful in that each of the number of metal rings constituting a CVT belt is corrected to a shorter peripheral length for the inner side of the metal ring and a longer peripheral length for the outer side of the metal ring. Therefore, the necessary peripheral length difference for layering the metal rings can be accordingly provided.

However, for example when foreign substances (residual pieces of cutting metal or the like) adhere to the surface of a metal ring in a preceding process (solution treatment or the like) prior to the correction process, the foreign substances cut into the roller surface of the peripheral length correction device, consequently creating a problem by causing damage to the rollers of the peripheral length correction device. Additionally, if the impaired roller is used as is a number of defective metal rings with damaged surfaces will be produced. Consequently, this creates a problem of reduced production yield.

#### SUMMARY OF THE INVENTION

The present invention has been made for the purpose of solving the circumstances mentioned above. Accordingly, the object of the present invention is to provide a peripheral length correction device which does not damage the rollers even if foreign substances (residual pieces of cutting metal or the like) have adhered to the surface of a metal ring in a preceding process (solution treatment or the like) prior to the correction process, and prevent diminished production yield.

The present invention pertains to a peripheral length correction device of metal rings, wherein a metal ring is laid on at least two rollers which are displaceable in mutually separating directions. One or both of the rollers are displaced while rotating the rollers, thereby applying tensile stress to the metal ring to correct the peripheral length thereof and is

characterized in comprising: a removal means for removing foreign substances adhered to the inner peripheral surface of the metal ring; and a re-adhesion prevention means for preventing re-adhesion of the foreign substances removed by the removal means to the metal ring.

According to the invention, when foreign substances (residual pieces of cutting metal or the like) are adhered to the surface of a metal ring in a preceding process (solution treatment or the like) prior to the correction process, the foreign substances are removed by the removal means, and re-adhesion of the removed foreign substances to the metal ring is prevented by the re-adhesion prevention means. Therefore, even if foreign substances are adhered to the surface of a metal ring, it is possible to prevent a reduction in yield by maintaining the quality of the metal rings without damaging the driving roller or the driven roller.

A preferred mode of the invention is that the removal means has an abutting body abutted on the inner peripheral surface of the metal ring with a predetermined pressing force.

According to this mode, by adjusting the pressing force applied to the abutting body to make it optimal, it is possible to effectively remove foreign substances; from a substance loosely adhered to the inner peripheral surface of the metal ring to a substance firmly adhered thereto.

The abutting body is a rotary brush made of a static free material.

According to this mode, costs can be reduced by simplifying the structure of the abutting body, and generation of static electricity can be prevented during removal of the foreign substances, whereby re-adhesion of the foreign substances can be prevented.

Alternatively, the re-adhesion prevention means suctions away the foreign substances removed by the removal means to prevent the re-adhesion thereof to the metal rings.

Corresponding to this mode, as the removed foreign substances are suctioned away by negative pressure or the like, it is possible to prevent the re-adhesion of the foreign substances as a result of its simple configuration.

Furthermore, the abutting body is driven by a predetermined driving mechanism. The driving mechanism can move the abutting body in the short direction of the inner peripheral surface of the metal ring laid on the rollers. The abutting body is moved so that the separating distance in the direction vertical to the inner peripheral surface of the metal ring can be increased as the moving distance in the short direction becomes larger.

In this mode, the pressing force of the abutting body can be adjusted by controlling the moving amount of the abutting body. Moreover, since the moving direction is set in the short direction of the inner peripheral surface of the metal ring laid on the rollers, it is possible to prevent interference between the metal ring and the abutting body by increasing the moving amount of the abutting body in the short direction when the metal

ring is handled to lay on the rollers.

The above and further objects and novel features of the present invention will more fully appear from the following detailed description when the same is read in conjunction with the accompanying drawings. It is to be expressly understood, however, that the drawings are for the purpose of illustration only and are not intended as a definition of the limits of the invention.

#### BRIEF DESCRIPTION OF THE DRAWINGS

FIGS. 1A to 1D are respectively a top view, a side elevation view, a main section enlarged view, and a main section perspective view of a peripheral length correction device of an embodiment.

FIG. 2 is a view of the positional relation between the rotary brush 5c and the metal belt 4 in the foreign substance removal position.

FIG. 3 is a constitutional view of the foreign substance removal head 5 and its related components.

FIG. 4 is a state diagram of the foreign substance removal position, the standby position, and the foreign substance removal head 5 in an optional position there between.

#### DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENT

The present invention will hereinafter be described in detail with reference to the preferred embodiments shown in the accompanying drawings.

FIGS. 1A to 1D are respectively a top view, a side view, a main section enlarged view and a main section perspective view.

In the drawings, the peripheral length correction device of metal rings 1 has a driving roller 2 and a rotation-free driven roller 3 which are rotary-driven by a drive means (not shown). The two rollers (driving roller 2 and driven roller 3) are displaceable in mutually separating directions. For example, a rotation axis position of one roller (hereinafter referred to as "driving roller 2") is fixed, and a rotation axis position of the other roller (hereinafter referred to as "driven roller 3") can be moved closer to or farther apart from the driving roller 2 within a predetermined range in a direction to the rotation axis of the driving roller 2. The driven roller 3 indicated by dotted figure lines in the drawing represents a position when it is moved closest to the driving roller 2 (hereinafter referred to as "closest position"). The driven roller 3 indicated by a solid line in the drawing represents a position when it is moved outermost from the driving roller 2 (hereinafter referred to as "outermost position").

Initially when a peripheral length correction process is carried out, the driven roller 3 is moved to the closest position to lay the metal ring 4 on the driving roller 2 and the driven roller 3. Then, after the driven roller 3 is moved toward the outermost position by a proper amount to take up the slack of the metal ring 4, the driven roller 3 is moved to the outermost position while the driving roller 2 is rotary-driven. In this

movement, applying pressure P on the driving roller 2 generates tensile stress on the metal ring in a peripheral direction, thus a peripheral length of the metal ring 4 can be extended (corrected) to a desired length through adjusting the amount of the pressure P and the applying duration thereof.

In the shown peripheral length correction device of metal rings 1, the two rollers (driving roller 2 and driven roller 3) are displaceable in the mutually separating positions and are displaced to apply the tensile stress to the metal ring 4. However, the device is not limited to this configuration. For example, a third roller (correction roller) may be added. This correction roller may be displaced to apply tensile stress to the metal ring 4 as shown in Japanese patent application number 2001-105050 described above.

The peripheral length correction device of metal rings 1 of this embodiment is provided with the aforementioned components necessary for the peripheral length correction process, and moreover comprises the following characteristic components comprising the foreign substance removal head 5 and its accessory components. That is, the foreign substance removal head 5 is constituted by mounting a rotary brush 5c inside a cylindrical head cover 5b which has an opening 5a formed on part of the side face, and inserting a rotary shaft 5d of the rotary brush 5c through the head support pipe 5e.

The head support pipe 5e has such a constitution as negative pressure is applied from a later described pneumatic pump. This

negative pressure is applied through the head support pipe 5e to the opening 5a of the head cover 5b to make it function as a suction port. The rotary brush 5c is rotary-driven in a predetermined direction by a later described rotary-driven section. The foreign substance removal head 5 can be freely moved between a shown position (hereinafter referred to as "foreign substance removal position") and a "standby position" (standby position when the metal ring 4 is installed) in a described below moving mechanism.

FIG. 2 is a view of a positional relation between the rotary brush 5c and the metal ring 4 in the foreign substance removal position. Now, assuming that foreign substances 4a (residual pieces of cutting metal or the like) are adhered to the inner peripheral surface of the metal ring 4 in a preceding process (solution treatment or the like) and the foreign substances 4a are left remaining in place, they will cut into the surface of the driving roller 2 or the driven roller 3 and damage the rollers. If the damaged roller(s) continues to be used, the metal ring 4 thereafter will be damaged when the peripheral length correction process is performed. These defective products are then rejected and directly cause a reduction in production yield.

According to the embodiment, the rotary brush 5c is rotated and abutted on the inner peripheral surface of the metal ring 4 by a proper pressing force making it possible to remove the foreign substances 4a adhered to the inner peripheral surface of the metal ring 4. Moreover, since the removed foreign

substances 4b are suctioned away by the negative pressure, it is also possible to prevent re-adhesion to the metal ring 4. Here, the material of the rotary brush 5c, a static free material such as horse hair or wool is preferably used. This material has the precise degree of toughness needed to remove the foreign substances 4a firmly adhered to the inner peripheral surface of the metal ring 4, is highly wear resistant, and no static electricity is induced by contact with the metal ring 4. Nylon or felt buff can also be used by being subjected to an antistatic treatment.

FIG. 3 is a block diagram of the foreign substance removal head 5 and its related components. In the drawing, the head support pipe 5e of the foreign substance removal head 5 is attached to a substrate 6. The rotary-driven section 7 of the rotary brush 5c and a moving mechanism section 8 of the foreign substance removal head 5 are disposed on the substrate 6. Both the rotary-driven section 7 and the moving mechanism section 8 use air pressure generated by a pneumatic pump 9 as a power source. That is, the rotary-driven section 7 provides the rotary-drive for the rotary shaft 5d of the rotary brush 5c by means of receiving the air pressure from pneumatic pump 9 (e.g., an air motor). The moving mechanism section 8 also receives air pressure to move the substrate 6 in both directions along a shown arrow 10, and can move the foreign substance removal head 5 integrated with the substrate 6 between a "foreign substance removal position" and a "standby position" or to an optional position

there between (e.g., an air cylinder).

The shown arrow 10 indicates a right downward oblique traveling direction on a drawing surface, which means the following. Namely, if the short direction of the inner peripheral surface of the metal ring 4 laid on the driving roller 2 and the driven roller 3 is LS, the foreign substance removal head can be moved along this direction LS. As the moving distance in the short direction LS is larger (downward movement on the drawing surface is larger), a separating direction (distance in a right direction LR on the drawing surface) in the vertical direction of the inner peripheral surface of the metal ring 4 can be increased. That is, the shown arrow 10 means the combined direction of LS and LR (a vector direction).

The pneumatic pump 9 is designed to generate air pressure necessary for the power source of the rotary-driven section 7 and the moving mechanism section 8, and negative pressure is applied to the opening 5a of the foreign substance removal head 5. The air pressure generated at the pneumatic pump 9 is supplied through flexible pipes 11 and 12 to each of the respective rotary-driven section 7 and the moving mechanism section 8 when necessary. Specifically, when the rotary brush 5c is rotated and when the substrate 6 is moved to the foreign substance removal position, the standby position or the optional position there between. The negative pressure generated at the pneumatic pump 9 is supplied through a flexible pipe 13 to the head support pipe 5e when removing the foreign substances that are suctioned

away.

FIG. 4 is a state diagram of the foreign substance removal head 5 in the foreign substance removal position, the standby position and the optional position there between. In the drawing, A indicates the foreign substance removal position, C the standby position, and B the optional position there between. When the foreign substance removal head 5 is in the foreign substance removing position (A), the rotary brush 5c is abutted on the inner peripheral surface of the metal ring 4 by a predetermined pressing force. The pressing force reaches maximum when the position (position along the direction of the arrow 10) of the foreign substance removal head 5 coincides with the foreign substance removal position (A). When slightly separated, the pressing force is reduced corresponding to the separating direction. Thus, simply by adjusting the moving amount of the substrate 6 by the moving mechanism section 8, it is possible to adjust the pressing force between the rotary brush 5c and the inner peripheral surface of the metal ring 4.

Additionally, when the foreign substance removal head 5 is in the standby position (C) or a position near the standby position (C), the foreign substance removal head 5 is positioned lower than the setting position of the metal ring 4 (position when it is laid on the driving roller 2 and the driven roller 3) in the drawing. Thus, as the foreign substance removal head 5 in the standby position does not interfere with the metal ring 4, it never stands in the way when the metal ring 4 is laid on

the driving roller 2 and the driven roller 3.

As apparent from the foregoing, the peripheral length correction device of metal rings 1 of the embodiment can provide the following advantages.

5           (1) First, the driven roller 3 is moved to the closest position when the metal ring 4 is laid on the driving roller 2 and the driven roller 3. Then the driven roller 3 is moved toward the outermost position by a proper amount to take up the slack of the metal ring 4. Subsequently, when the driving roller 2 is  
10           rotary-driven and the driven roller 3 is moved toward the outermost position, pressure P is applied to the driving roller 2 while moving, whereby tensile stress can be applied in the peripheral direction of the metal ring 4. As in the case of the conventional technology, by adjusting the amount of pressure P and the duration  
15           of application thereof, the peripheral length of the metal ring 4 can be extended (corrected).

          (2) The rotary brush 5c is rotated and abutted on the inner peripheral surface of the metal ring 4 by a proper pressing force, whereby the foreign substances 4a adhered to the inner peripheral  
20           surface of the metal ring 4 can be removed. Moreover, since the removed foreign substances 4b are suctioned away by the negative pressure, re-adhesion thereof to the metal ring 4 can also be prevented.

          (3) The rotary brush 5c is abutted on the inner peripheral  
25           surface of the metal ring 4 by the predetermined pressing force. Although the pressing force reaches its maximum when the position

of the foreign substance removal head 5 (position along the direction of the arrow 10) coincides with the foreign substance removal position (A), when slightly separated, the pressing force is reduced corresponding to the separating distance. Thus, simply by adjusting the moving amount of the substrate 6 by the moving mechanism section 8, it is possible to adjust the pressing force between the rotary brush 5c and the inner peripheral surface of the metal belt 4.

(4) When the foreign substance removal head 5 is in the standby position (C) or in a position near the standby position (C), the foreign substance removal head 5 is positioned lower than the setting position of the metal ring 4 (position when it is laid on the driving roller 2 and the driven roller 3). Thus, since the foreign substance removal head 5 in the standby position does not interfere with the metal ring 4, it never stands in the way when the metal ring 4 is laid on the driving roller 2 and the driven roller 3.

According to the embodiment, the foreign substances are removed by using the rotary brush 5c. However, the invention is not limited to this as an abutting body other than the brush may be used. However, generally in the metal rings of a CVT belt, curves (also referred to as "crowning") are frequently formed in its sectional direction as contrivance of alignment during layering. Therefore, a preferable component such as a brush where the abutting portion is freely deformed is used from the standpoint of "fittability" to the curved surface.

Furthermore, according to the embodiment, the rotary-driven section 7 is fixed to the substrate 6. However, in the form of the above operation if the rotary-driven structure is attached to the substrate 6 through an elastic body, such as a coil spring to enable setting adjustment of the elastic body, the pressing force of the rotary brush 5c to the metal ring 4 can be varied. By such a structure, foreign substance removal effect may be adjusted when necessary.

According to the present invention, if foreign substances (residual pieces of cutting metal or the like) are adhered to the surface of a metal ring in the preceding process (solution treatment or the like) prior to the correction process, the foreign substances are removed by the removal means, and re-adhesion of the removed foreign substances to the metal ring is prevented by the re-adhesion prevention means. Therefore, even if foreign substances are adhered to the surface of a metal ring, it is possible to prevent a reduction in production yield by maintaining the quality of the metal rings without damaging the driving roller or the driven roller.

According to the preferred mode of the present invention, by adjusting the pressing force applied to the abutting body to make it optimal, it is possible to effectively remove foreign substances ranging from substances loosely adhered to the inner peripheral surface of the metal rings to substances firmly adhered thereto.

Costs can be reduced by simplifying the structure of the
